Polimetrics

Lecture 1

What we mean by preferences of political actors: an introduction
NOT SURE IF POLITICAL OPINIONS ARE DISGUSTINGLY UNINFORMED

OR PAINFULLY STUPID
Overview

1. Why measuring preferences?
2. The notion of distance: from a one- to a multi-dimensional policy world
3. Distance and rationality
It all began with…

Can we (really) think about politics in a non-spatial way?

Positions, Distance, Movement, Direction…
It all began with…positions!

Most people who talk about politics are likely to talk sooner or later about the “positions” of political actors.

- It is difficult if not impossible to have a serious discussion about the substance of real politics without referring to “where” key actors stand on substantive matters at issue.
It all began with...positions!

Systematic description of individual policy preferences are therefore grounded in the notion that a political actor has an ideal or most-preferred policy with regard to a particular issue, and that other policy options can be systematically compared to this “ideal point” in terms of their “closeness” to it.
From positions to...distance

The very notion of position implies the notion of distance

- If you want to describe the positions of two key actors, you need to make sooner or later at least an implicit statement that these positions are either “the same” or “different”

- If they are different, it is difficult not to have some intuitive sense of whether they are somewhat different or very different
From positions to...distance

This intuition can become more systematic when describing the positions of three or more actors

- Now, it is possible to make substantively meaningful statements such as “Churchill and Roosevelt are closer together on this matter than are Churchill and Stalin”
The very notion of **distance** implies the notion of **movement**

- It is very common when discussing about politics to talk about people “**changing**” their positions on some important matter, with the result that they are now “**closer to**” or “**farther away from**” some other person than they were before.
From positions to distance to...movement

Once again, this is part of a common language people use when they talk about politics. Indeed, most political debate has to do with some people trying to change the positions of others on important matters at issue.
The very notion of movement implies the notion of direction

- If my position moves closer to yours on some matter at issue, I have moved “towards” you on that matter
- All movement is relative. I can only observe and describe your movement relative to some benchmark
From positions to distance to movement to...direction

For example...
From positions to distance to movement to...direction

...it seems to be uncontroversial that the British Labour Party under the leadership of **Tony Blair** moved “towards the center”, and “away” from the more “left-wing” position it had occupied before. And now, under the new leadership of **Jeremy Corbyn**, things are changing once again.
Can we (really) think about politics in a non-spatial way?

DIFFICULT indeed!!!
The spatial metaphor

Spatial representations of the structure of political action are no more than a set of conventions that stress the relevance of concepts such as positions, distance, movement, direction when dealing with political interactions and relationships!!!
Why caring? An example

The capacity to locate for example political parties within a well-defined common space allows us to compare parties and party systems both cross-nationally and over time.

1. It allows us to compare party positions, their similarities, their evolutions, as well as to contrast parties according to a variety of characteristics (electoral performance, government role, stability, etc.)

2. It helps us to compare party systems in terms of their degree of polarization, the direction of competition, the degree of convergence, etc.
It all began with…

3. It allows us to understand the dynamics, structure and **consequences of party competition**

4. It helps us to understand the working and effectiveness of **representative government**. For example, by comparing parties’ positions to the preferences expressed by voters, we can gain a real and measurable sense of the extent to which these two core components of representative government are mutually congruent
Spatial models and Utility

Spatial models conceptualize individual utility over a particular alternative as maximized when the location of that alternative is identical to an individual’s ideological ideal point.

Utility monotonically decreases as the distance between the alternative and the individual’s ideal point increases.

This brings us directly to the very notion of distance.
In an abstract theoretical sense, the structure of policy preferences in any political system can only be described by using a policy space of **very high dimensionality**, spanned by all potential policy dimensions (economic, social, foreign policy, etc.)

In practice, analysts usually confine themselves to policy spaces defined by a small set of “**salient**” policy dimensions
Dimensions matter!

Typically, the dimensions deemed salient are few (1 or 2): most theorists are apt to fix the dimensionality of the policy space that they use in their analysis by fiat.

Yet, the dimensionality of a policy space has a fundamental impact on theoretical analysis (as we will see later…)

Moreover, when we move from 1 to 2 dimensions, also the meaning of “distance” becomes more complex. Let’s see how…
One dimension? No problem!

The key distinctions between different ways of measuring political similarity and difference collapse when only one dimension of difference is considered important.

In this case there is only **ONE way** to measure the distance between two points: the **length of the segment dividing them**.
Dimensions matter!

From 1 to 2 dimensions…

The dimensionality of the policy space involves the assumptions that are made about how people trade-off distance from their ideal point on one dimension against equivalent distances on the other dimensions
Dimensions matter!

From 1 to 2 dimensions…

This shows up **empirically** as a decision that must be taken over the **metric** to be used when measuring how a given individual perceives the policy distances between two points in a multidimensional policy space: we need to derive an overall indication of the «**policy distance**» between two points in such multidimensional space.
Dimensions matter!

Overhelmingly the most common assumption is that distances on different policy dimensions are traded off in a manner that is directly analogous to the trading off of distances in physical space. In other words, it is assumed that individuals view the interaction between policy dimensions in Euclidean terms.
Dimensions matter!

According to Euclidean distance, the distance between two points is simply the result of...the Pythagorean Theorem!!!

That is...the square root of the sum of the squares of the distances between two points on each dimension
Dimensions matter!

A (1, 3)

B (4, 7)
Dimensions matter!

\[ c^2 = a^2 + b^2 \]

\[ c = \sqrt{a^2 + b^2} \]
Dimensions matter!

\[
\sqrt{(1 - 4)^2 + (3 - 7)^2} = 5
\]

A \((1, 3)\)

B \((4, 7)\)
Dimensions matter!

The great advantage of the assumption of Euclidean preferences is that it allows policy space to be described and analysed in terms of a familiar geometry.

It also allows us to describe how person A feels about policy X in terms of a circular «indifference curve» centred on A and passing through X.

Everything inside the curve is preferred by A to X.
Dimensions matter!
Dimensions matter!

Alternative to Euclidean preferences:

City Block geometry measures the distance between two points in a multidimensional space by simply adding their distances apart on each dimension.

Why «city-block metric»?
Dimensions matter!

The city-block metric is so-called because the effective distance between two points in a city must be measured in terms of movement that can take place only along the «dimensions» defined by the alignment of the city blocks.

Since diagonal movement is not possible given city blocks, the Euclidean metric makes misleading estimates of the effective distance between two points in a city.

The indifference curve of an actor in two dimensions is not anymore a circle, but a square.
Dimensions matter!
Dimensions matter!

A considerable body of empirical psychological research suggests that the City Block metric fits human behavior better when the dimensions of difference are “separable,” and the Euclidean metric when they are “integral”

“Separable” dimensions: similarity on one dimension can be assessed quite independently of similarity on the other

“Integral” dimensions: similarity on one dimension cannot be assessed without regard to similarity on the other (e.g., such as allocation decisions with a fixed budget)
Dimensions matter!

Both the Euclidean and the City Block metric are special cases of a more general metric, the **Minkowski metric**, which defines the distance between a pair of points in terms of the distance between the coordinates of these points on salient dimensions.

The distance $d_{AB}$ between two points A and B, measured using the Minkowski metric, is

$$d_{AB} = \left( \sum_{i=1}^{n} |X_{iA} - X_{iB}|^r \right)^{1/r}$$

Where $r$ is the **order of the metric**. In an Euclidean world, $r=2$. In a city block world, $r=1$; etc.
Dimensions matter!

The widespread use of Euclidean spatial representations by the current generation of political scientists is a matter of convenience, convention and mathematical tractability.
Issue of salience

Up to now we have assumed that actors attach equal importance to both dimensions in a multi-dimensional space. Still this should not be always the case. It could happen that for one person, a dimension (such as economy) is twice as important as the second one (such as the social one).

Which implications?

Now distances on the economic dimension have twice as much weight in calculations of the distance between two points as do distances on the social dimension.
Issue of salience

Therefore, for any individual we need to know both her position on some particular dimension of interest and the **importance** she attaches to this dimension relative to other dimensions of interest.

This allows us to capture the **different views** that people may have of the same underlying spatial map.

The indifference **curve** of actors now are **elliptic curves**.
In this case, economic policy is **twice as important** than social policy for actor A (no elliptic curve: $X=Y$; elliptic curve: $X'<Y'$ – i.e., Actor A evaluates exactly in the same way the two segments, despite their different length!)
In this case, social policy is **twice as important** than economic policy for actor A (no elliptic curve: $X=Y$; elliptic curve: $X'<Y'$ – i.e., Actor A evaluates exactly in the same way the two segments, despite their different length!)
Space, distance and rationality

Using spatial representations of policy preferences involves making **assumptions** about the **rationality** of those political actors whose views are being modelled.

Representing preferences of political actors within a space, implies implicitly that you assume that such actors have **complete and transitive preferences**... that is, they are **rational actors**!
**Space, distance and rationality**

**Assumption of completeness**: the political actor is assumed to make her choices in accordance with a complete preference ordering over the available options (in the space)

**Assumption of transitivity**: If alternative A is (weakly) preferred to alternative B, and B (weakly) to C, then A is (weakly) preferred to C
Space, distance and rationality

Try to geometrically map such matrix of Euclidean distance between actors A, B and C (where, for example, 4 is the distance between B and C, and 3 is the distance between A and the C, etc.)

<table>
<thead>
