Classification methods

Structural Topic Model (STM) innovates on Topic models in two different ways:

First: topic proportions (θ) are allowed to be **correlated**: this is a reasonable assumption given that in documents topics discussed are correlated!

For example, if a party manifesto contains discussion of Topic X (e.g. administrative reform), the probabilities that it will also contain discussion of Topics Y (e.g. curbing public works) and Z (e.g. reducing the number of Lower House members), are not independent of each other, but correlated

In this sense, STM fits a Correlated Topic Model

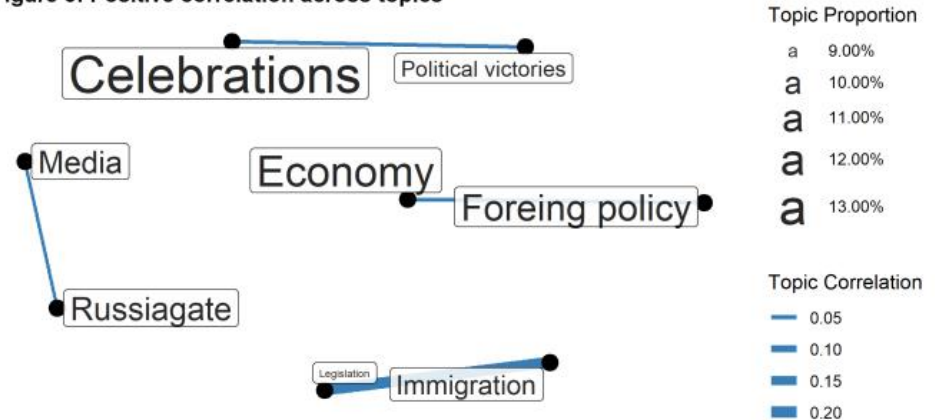

Classification methods

Graphical depictions of the (*positive*) correlation between topics provide insight into the organizational structure at the corpus level

In essence, the model identifies when two topics are likely to co-occur (by focusing on positive correlation) within a document

Classification methods

Second: as we already discussed, topic models allow the analyst to estimate for each document the proportion of words attributable to each topic, providing a measure of *topic prevalence*

These models also calculate the words most likely to be generated by each topic, which provides a measure of *topical content*

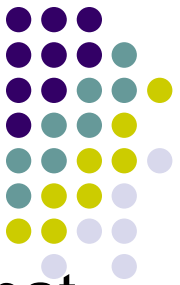

Classification methods

However, in standard LDA, the document collection is assumed to be **unstructured**; that is, each document is assumed to arise from the same data-generating process irrespective of additional information (about the corpus) the analyst might possess

But that shouldn't be always the case...

Classification methods

Suppose for example that you have reasons to believe that the **age** of a text's author affects the *probability to discuss about a given topic* rather than some other alternatives

Or that author's age affects the *probability of using some words when discussing about a given topic* rather than others

How to incorporate such information (i.e., *such structure*) directly in the analysis?

Classification methods

You cannot do that via standard Topic Models...but yes in a STM! That's precisely the second (and crucial) innovation of a STM

In a STM each document can have its own prior distribution over topics according to the document-level variables you decide to include in the fitted topic model (i.e., **topical prevalence** – the *thetas* – can be affected by the covariates you include in the topic model), rather than sharing a global mean

Same things happen for **topical content**, i.e., the *betas* of your fitted topic model

Classification methods

That is...

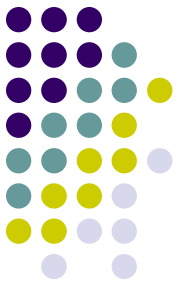

...rather than assuming that **topic prevalence** (i.e., the frequency with which a topic is discussed) and **topical content** (i.e., the words used to discuss a topic) prior distribution **are constant** across all documents...

...the analyst can incorporate covariates over which we might expect to see variance directly when estimating the topics

Through this, we can obtain measures of how our treatment condition systematically affects how often a topic is discussed (prevalence)!

Classification methods

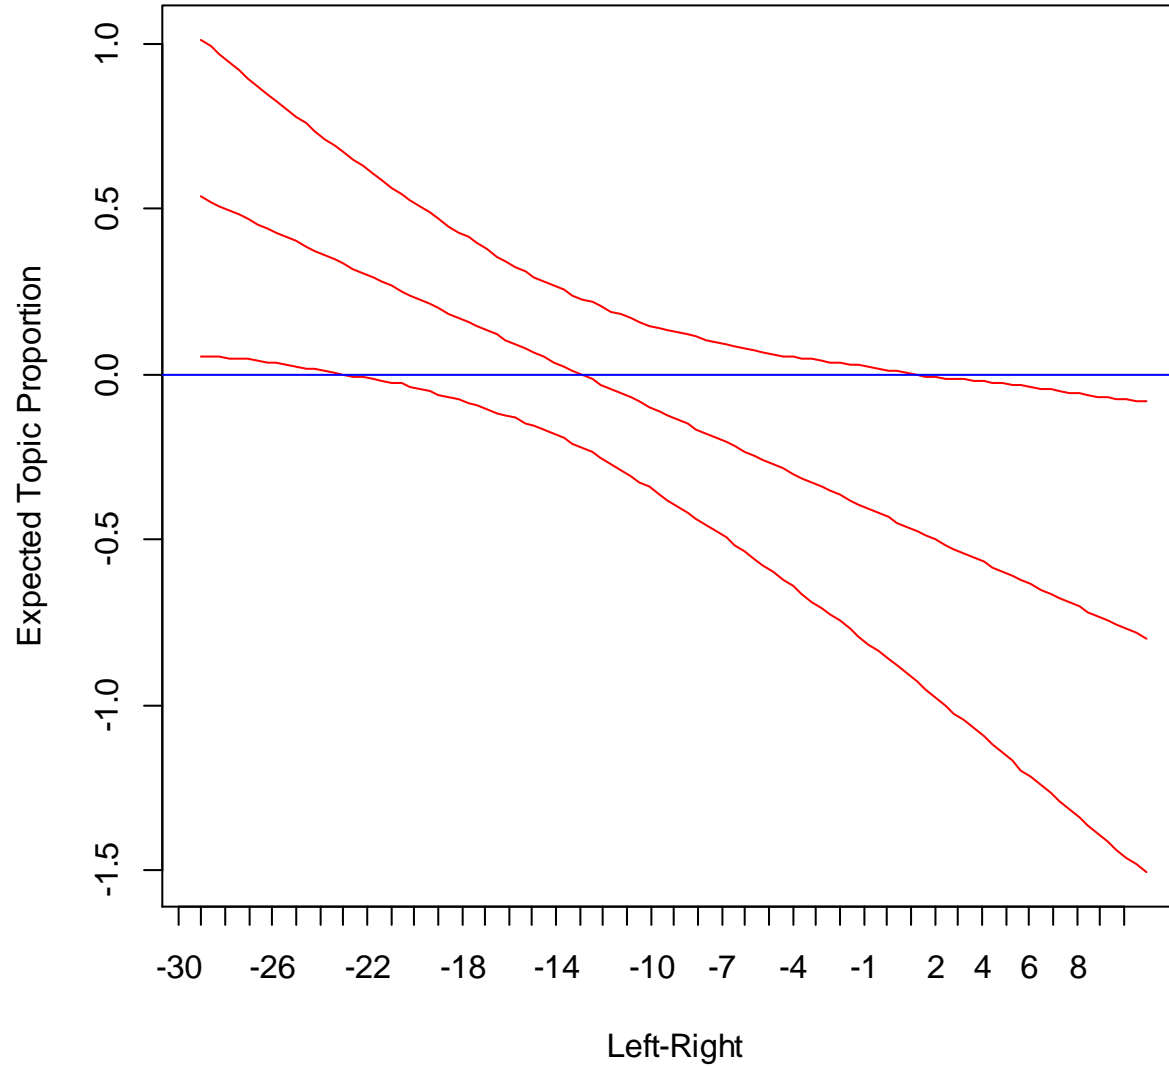

- for example, do documents of **left parties (or opposition politicians)** discuss more about a given topic than documents of right parties?

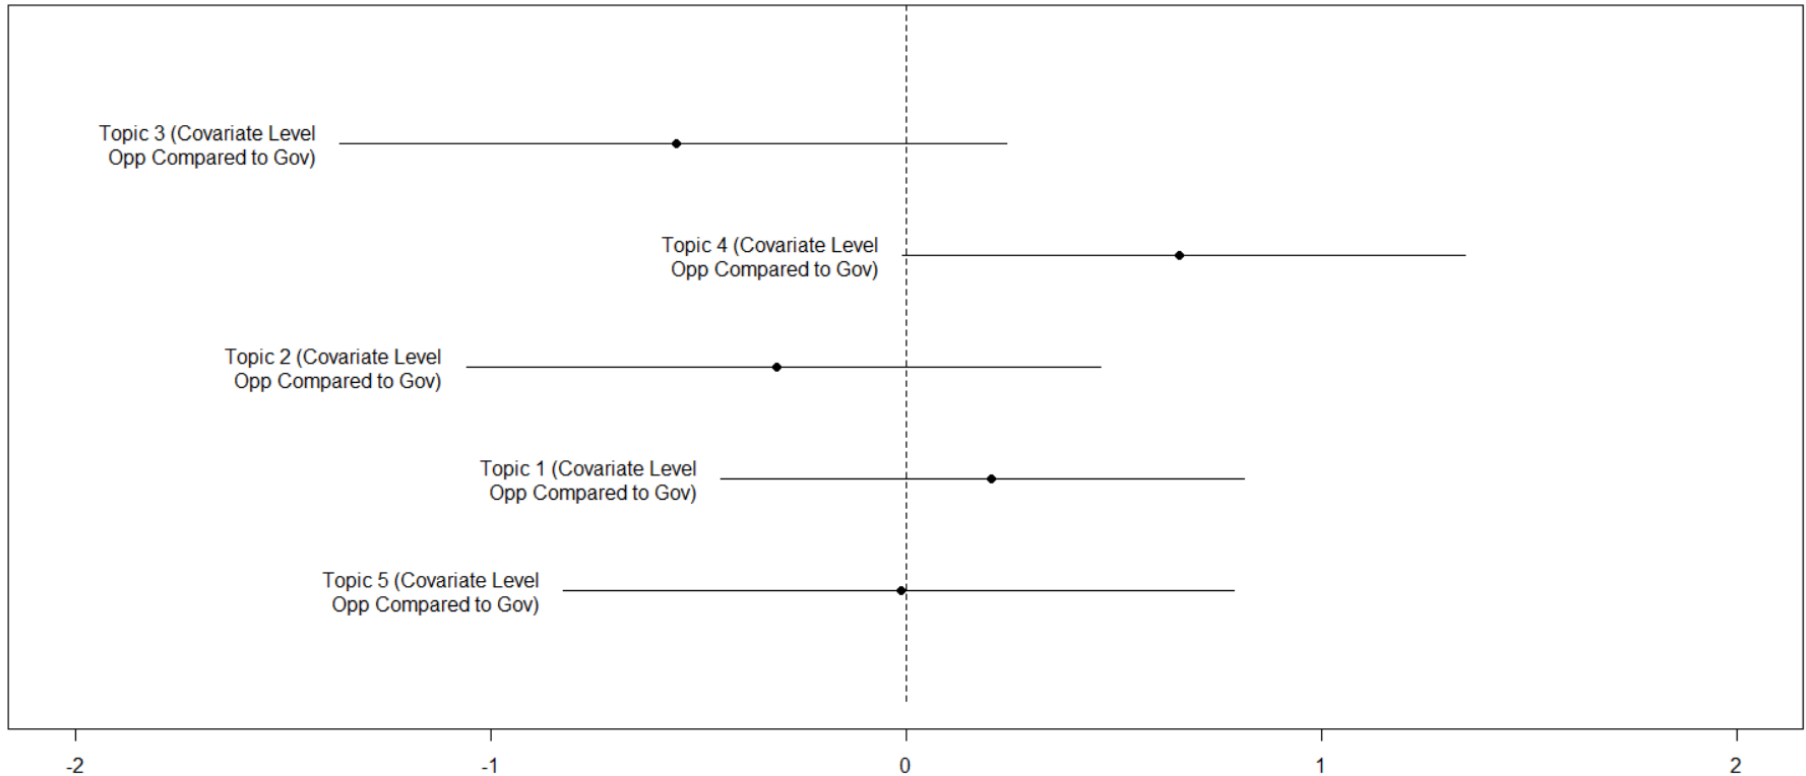

Classification methods

Topic 4: over LR

Classification methods

Reported coefficient:
«opposition – government»

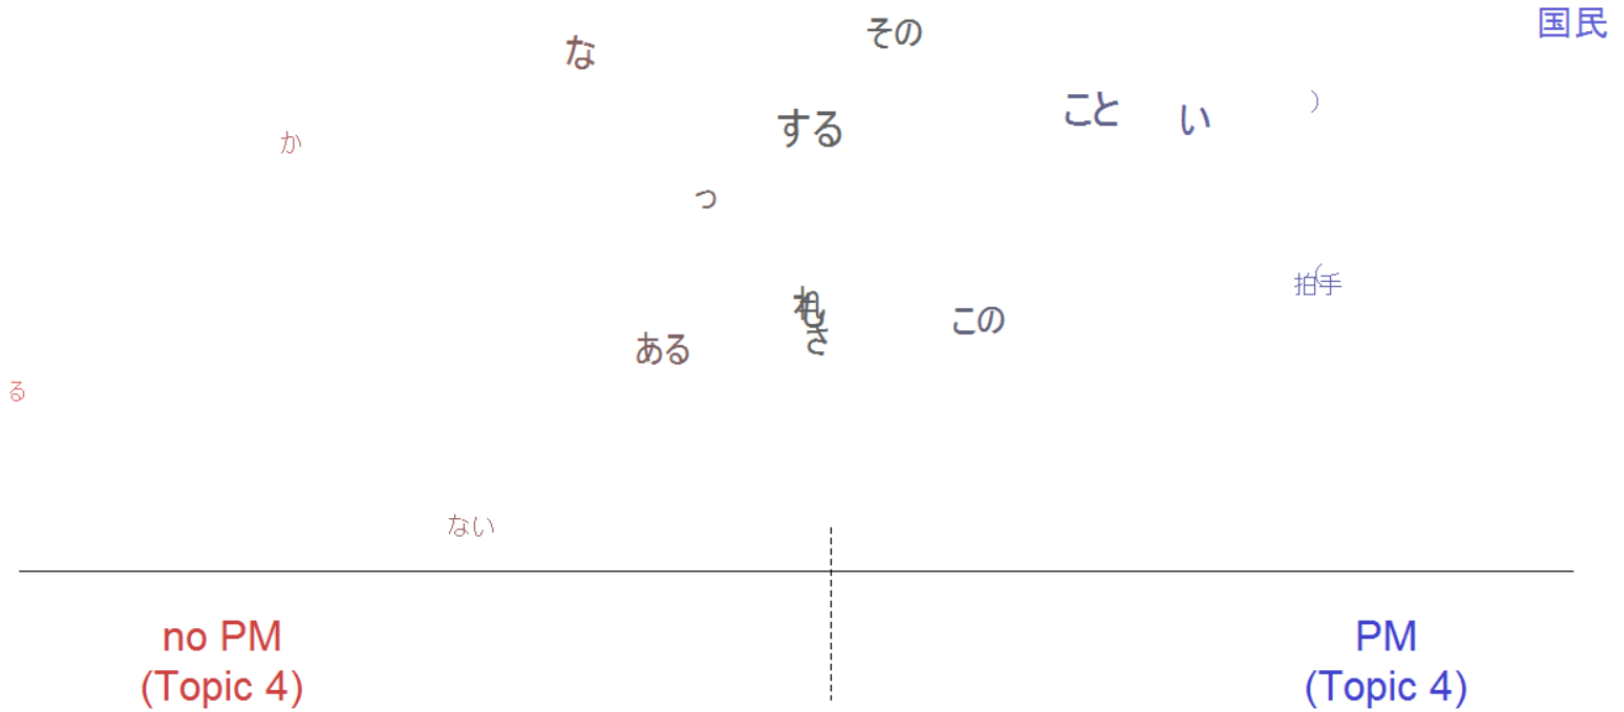

Classification methods

Moreover, we can obtain measures of how the **language** used to discuss the same topic (content)

- for example, when **men** politicians discuss about a particular topic do they use the same words than **female** politicians?

Classification methods

Classification methods

In the STM framework, the researcher has therefore the option to choose covariates to incorporate in the model

These covariates inform either the **topic prevalence** or the **topical content** latent variables with observed information about the respondent

Classification methods

The analyst will want to include a covariate in the **topical prevalence portion of the model** when she believes that the observed covariate will affect *how much* the respondent is to discuss a particular topic

The analyst also has the option to include a covariate in the **topical content portion of the model** when she believes that the observed covariate will affect *the words which a respondent uses* to discuss a particular topic

These two sets of covariates can overlap, suggesting that the topic proportion and the way the topic is discussed change with particular covariate values

Classification methods

Given an unstructured Topic Model...

...you can still try to control if there is there any relationship between for example the *ideology of the writer of a document* and the emphasis/salience she devotes in her document(s) towards a particular topic (for example, a topic about social welfare or migrants)

But you can do it...

...only after you have ended to run the Topic Model and obtained the θ s

Classification methods

Such θ s have been moreover generated by assuming that they arise from the same data-generating process - irrespective of any document-level variables of interest

On the contrary, STM by relaxing this assumption, allows you to estimate **simultaneously** the θ s and the possible impact on their variance across documents of some document-level variables of interest!

As a result, it is much more efficient as an approach!
